Abstract: The fractal approach allows to extend the knowledge about the nonlinear dynamics evolution caused by the growth of capacity and adequacy of information about regularities, uncertainties and abnormalities. The paper applies the fractal approach to analyze the instrumental time series observing the air temperature of the land surface during 1902-2012 years. An annual warming-cooling cycle is considered as a unit, so the peculiarities of the viewpoint on the temperature dynamics are connected with the analysis of the time series profiles. The corresponding fractal model – described the annual warming-cooling cycle dynamics - is adapted to the considered subject. Then it becomes possible to study comparatively the averaged, extremely and amplitude-frequency characteristics of the annual warming-cooling cycles. The observations – completed in the forty meteorological stations – are used in the six quasi-homogeneous climate regions. The individual and comparative study of the local climate systems exhibits both over-regional dominant tendencies and local uncertainties that enable to learn the local climate dynamics in more details. *Copyright © Research Institute for Intelligent Computer Systems, 2015. Keywords: approach, time-series analysis, land surface air temperature observations, annual warming-cooling cycle, dominant tendency, local abnormality.

1. INTRODUCTION

The practical question how to analyse the climate dynamics in a certain geographic point for a season or few (up to three) years with high accuracy remains open till now [1, 2] because the annual warming-cooling cycle profile is supposed to be considered at least. What data and methods there are to solve the problem? The abilities of climate models to simulate the surface air temperature diminish when the coverage in time or place reduces [3]. The data of instrumental measurements seem to be the most reliable in this case, but the available instrumental data can be substantially restricted in size and resolution over time or/and space. In particular, the paleo-climate data allows to consider the surface air temperature evolution in timescales from hundreds years to millions years [4, 5], but the temperature variation within an annual warming-cooling cycle is not considered. The meteorological data contains the information concerning the temperature variation within an annual warming-cooling cycle, but the reliable meteorological data is, usually, about centenary long and no longer 300 years [6, 7].

To use the meteorological data it is necessary to find a compromise between methods of data acquisition and the coverage in time and space. The global mean surface temperature exhibits the substantial inter-annual variability, where the temperature trends based on short-term observations are sensitive to beginning and end dates, and do not show long-term climate tendencies [3]. The climate models show similar results: trend estimations can be significantly different in relation to the same region but several timescales [8, 9], or can be significantly different in relation to the same timescale but several regions [10, 11]. In other words, the more space or timescale is considered in detail, the more number of exclusions in regional homogeneity can be founded. To analyse the dynamics of the annual warming-cooling cycles it is necessary to take into account the year-to-year variability of the cycles in frequency and amplitude characteristics [8, 10, 12]. Thus, the land surface air temperature observations should be considered as the nonlinear non-stationary noisy time series with complex profiles.

In this case the method of averaging can lead to distortions or losses of the actual information.

Nevertheless the averaging and linear trends remain the most useful to show the dominant tendencies in dynamics of the surface air temperature [3]. How to skirt around the disadvantage of the averaging? One of the ways is proposed in the paper. Namely, the fractal approach [13, 14] to analyse the dynamics of the instrumental time series with the complicated profiles is applied to estimate the dynamics of both temperature extremums and amplitude-frequency characteristics of the annual warming-cooling cycles. The corresponding fractal model to describe the warming-cooling cycle dynamics is introduced in section 2. The fractal model is aimed to convert the initial temperature time series into the succession of the units, which are similar in general but can be different in dimensional modifications [15, 16]. It allows to consider the dynamics of a local climate system in more detail. The results of the comparative analysis of the forty local climate systems are presented in section 3. Here the revealed over-regional dominant tendencies and the reasonings on

the peculiarity and abnormality of the local climate dynamics are summarized. Finally, conclusion is presented.

2. FRACTAL VIEWPOINT ON ANNUAL WARMING-COOLING CYCLE

Let us consider the short-term warming-cooling cycles made by the instrumental measurements that are similar to the long-term warming-cooling cycles based on paleo-climate data. Then the notion of an annual warming-cooling cycle (Fig. 1(a)) means a part of time series between the successive temperature minimums (hereafter T_{min}), where the time series consists of the land surface air temperature observations averaged per day (hereafter T). Let us consider the peculiarities of the annual warming-cooling cycles from the following practical point: how to estimate when and what temperature extremums (hereafter T_{min} and T_{max}) will occur in the nearest future (Fig. 1(a))?

Fig. 1 – A part of T -time series to illustrate the notion of annual warming-cooling cycle (a); characteristics of an annual warming-cooling cycle (b); the ranges of the temperature extremums in Tomsk (WMO-index 29430) over 1902-2012 years (c). The historical meteorological data here and after were provided by Russian Research Institute of Hydrometeorological Information – World Data Center, www.meteo.ru.

Let $dmin$ and $dmax$ be the time coordinates of T_{min} and T_{max} correspondingly; let $tmin$ and $tmax$ be the temperature coordinates of T_{min} and T_{max} correspondingly (white points in Fig. 1(b)). Then T -time series can be considered as the alternations of the extremums, where the triangle-like units are formed between the successive T_{min} -values (solid lines in Fig. 1(a)). Such process was denoted as the time series fragmentation [15], where each fragment represents a geometrical invariant with the fractal properties [13, 16]. At the same time, each fragment represents the linearized annual warming-cooling cycle. Then the model of T -time series based on the fragmentation is hereafter denoted as a fractal model. The fractal model will be described hereafter by the following characteristics of each annual warming-cooling cycle (Fig. 1(b)): the time and temperature coordinates of the extremums ($dmin$, $dmax$ and $tmin$, $tmax$); the averaged temperature ($tmean$), amplitude ($ampl$) and duration ($period$) in relation to the corresponding fragment; the relative duration of the warming stage (k).

Why it is necessary to find other models in addition and/or instead of the traditional one? Climate dynamics is analyzed in terms of the phase variables (first of all, temperature) averaged by year or more, but the consensus of opinions on the averaging is absent even today [8, 12, 17]: average over what and in what way? For example, the decadal timescale is considered as one of the most promising [1, 2]. Both 10-year and 20-year windows in relation to the reference period 1986-2005 years are used in the recent report of Intergovernmental Panel of Climate Change [3]. At the same time, the climate dynamics remains to be estimated by 30-year windows in relation to the reference period 1961-1990 years according to the current meteorological convention [17, 18]. The average concerns the notion of one year rather than the notion of the annual warming-cooling cycle. So, the annual dynamics of a local climate system is usually described by the temperature variation averaged per month. Correspondingly, the annual temperature variation maps traditionally 12 states of a local climate system between the successive minimums in January (for the Northern hemisphere), for example [12, 19, 20].

However the frequency and amplitude characteristics of annual warming-cooling cycles can be essentially variable [8, 10, 12]. In particular, $dmin$ -variation leads to that, that T_{min} -values can be observed beyond January. For example, $dmin$ -range can be from the November 19 to the March 11 (Fig. 1(c)). If the border of an averaging window is fixed (for example, the 1st of January), then a particular T_{min} -value can miss the averaging window (for example, the first and fourth fragments in

Fig. 1(a)). Or two T_{min} -values can hit the same averaging window (for example, the third fragment in Fig. 1(a)). So, the $ampl$ - and $tmean$ -values identified in a certain year will be different from the actual ones within the corresponding annual warming-cooling cycle. Such cases are not unique over last 111 years, and can occur several times successively. In particular, the range of $period$ -values can be estimated from 75% to 125% of one year, and the range of $ampl$ -values can be estimated from 66% to 100% of the maximal observable amplitude for example in Tomsk (Fig. 1(c)). Generally, the chaotic-like variation of the characteristics of the annual warming-cooling cycles in wide ranges seems to be natural over last hundred years at least. For example, the ranges of $tmax$ -, $tmin$ -, $dmax$ -, $dmin$ -values are illustrated in Fig. 1(c), where the $dmin$ -range is about 30% of year and the $dmax$ -range is about 20% of year. Similar results regarding 1902-2012 years can be illustrated for all the forty meteorological stations considered in the paper.

As a result, the fixed 1-year window can distort the description of annual temperature tendencies. For example, let us consider $tmean$ - and $dmin$ -time series (Fig. 2) to illustrate the differences of the results calculated per year and per fragment.

Fig. 2 – Examples of $tmean$ - and $dmin$ -time series (a,b correspondingly) calculated per year and per fragment in Tomsk over 1991-2012 years.

The profiles of *tmean*-time series calculated per year are smoother than the ones calculated per fragment; correspondingly, there are the distortions of the real extremums at least (Fig. 2(a)); *dmin*-trends calculated per year and fragment can be contrary in sign (Fig. 2(b)), correspondingly, the forecasts can be quite different. If it is necessary to analyse the dynamics of more than one local climate system, then it is necessary to choose a common averaging window to keep the correctness of the comparative analysis. For example, in the case of six meteorological stations the averaging windows should be chosen from the 1 May to the 1 October. Strictly speaking, the elements formed by 1-year window remain heterogeneous in shape to a greater or lesser extent. For example, the sketches of 1-year elements are illustrated in Fig. 1(a). From the mentioned viewpoint the fractal model seems to be more proper to describe the observed dynamics.

3. OBTAINED RESULTS

Let us use the fractal model to analyse forty meteorological stations located in six quasi-homogeneous climatic regions of East Europe, Siberia and Far East. The temperature measurements made at these stations are uninterrupted over the same timescale of 111 years long. The historical meteorological data were provided by Russian Research Institute of Hydrometeorological Information – World Data Center. The dynamics of each local climate system is analyzed by the following way: the characteristics of the annual warming-cooling cycles are determined for each fragment; the evolution of each characteristic is presented as one of the constituents of the local climate dynamics; the linear trend coefficient (hereafter index) is determined for each constituent. So, each *T*-time series is presented as the ensemble composed of the seven constituents (*dmin*-, *dmax*-, *tmin*-, *tmax*-, *ampl*-, *tmean*-, *k*-time series), which are estimated by the corresponding *dmin*-, *dmax*-, *tmin*-, *tmax*-, *ampl*-, *tmean*-, *k*-indexes. The ensemble viewpoint exhibits potentially more particularities concerning the evolution of time series [14, 21].

What it means in relation to temperature time series? Let us consider several examples. In particular, the following over-regional dominant tendencies were revealed on the basis of the index combinations (hereafter index scheme): the increase in the averaged temperature (i.e. the positive *tmean*-index) is realized with the decrease in the temperature amplitude (i.e. the negative *ampl*-index), the increase in the temperature minimums

(i.e. the positive *tmin*-index), and the decrease in temperature maximums (i.e. the negative *tmax*-index). And the moments of temperature minimums and maximums become to be later, i.e. the positive *dmin*- and *dmax*-indexes take place. The corresponding index scheme is illustrated in Fig. 3(a).

But it is just one of the index schemes. Mentioned combination of the temperature indexes can be realized with the negative *dmin*- and *dmax*-indexes in, for example, Eniseysk (WMO-index 29263). It is interesting that different index schemes can be observed not only within the same quasi-homogeneous climatic region, but also for the stations at a quite short distance. Each of the considered climatic regions seems to be rather heterogeneous from the viewpoint of the warming-cooling cycle dynamics. It confirms the known heterogeneity in short-term timescales regarding the temperature trends in North America shown in [11], regarding the rainfall extremes in West Europe shown in [22], as well as regarding the opposite temperature tendencies in timescales of ten thousands years [23]. The fractal model reveals that annual warming-cooling cycles can demonstrate not only more rapid rise in temperature, but also more rapid fall in temperature. It confirms the conclusion in [10], that annual warming-cooling cycles are characterized by variable periodicity in short-term timescales. But it is interesting, that similar variability of warming-cooling cycles is typical in more long timescales of ten thousands years [4, 5].

How the fractal analysis can be used differently? Let us continue to consider the local dynamics in Tomsk, and analyse the index scheme in Fig. 3(a). First, it allows to limit the ranges of the annual variation: the negative *tmax*-index means that the largest temperature maximum is no more than $M_{tmax} + 3\sigma_{tmax}$ (L1-line in Fig. 3(b)), where M is a mathematical expectation, σ is a root-mean-square deviation, the subscript denotes the corresponding constituents; the positive *tmin*-index means that the temperature minimum is no less than $M_{tmin} - 3\sigma_{tmin}$ (L2-line in Fig. 3(b)). The positive *dmin*-index allows to limit the earliest moment of the temperature minimum (L3-line $M_{dmin} - 3\sigma_{dmin}$ in Fig. 3(b)), and the positive *dmax*-index allows to limit the earliest moment of the temperature maximum (L4-line $M_{dmax} + 4\sigma_{dmax}$ in Fig. 3(b)). The latest moments of both temperature minimum and maximum are more uncertain: regarding the nearest future it is accepted only approximately as $M_{dmin} + 4\sigma_{dmin}$ and $M_{dmax} + 4\sigma_{dmax}$, correspondingly (dashed L5-, L4- lines in Fig. 3(b)).

Fig. 3 – Index schemes to summarize the pattern of the dominant tendencies in Tomsk over 1902-2012 years (a) and an example of the corresponding consequences from such local evolution (b).

Second, the characteristics allow to specify the limits of the acting dynamics and indicate the potential possibilities to forecast. In particular, the negative *ampl*-index means that the temperature difference between the neighboring extremums is no more than $M_{ampl} + 3\sigma_{ampl}$ (the vertical two-sided arrows in Fig. 3(b)). The positive *k*-index means that the duration between the minimum and maximum is no less than $M_k + 3\sigma_k$ days (the horizontal two-sided arrows in Fig. 3(b)). So, as soon as *L5*-line is crossed over (Fig. 3(b), at the moment *day*₁), it becomes possible to make more certain the characteristics of the temperature maximum ($T_{max\ i}$) in value and time within the running warming-cooling cycle: no more than $tmin_i + (M_{ampl} + 3\sigma_{ampl})$ and no earlier than *L6*-line. As soon as *L4*-line is crossed over (Fig. 3(b), at the moment *day*₂), it becomes possible to make more certain characteristics of the temperature minimum ($T_{min\ i+1}$) in value and time within the next warming-cooling cycle: no less than $tmax_i - (M_{ampl} + 3\sigma_{ampl})$, and no later than *L5*-line, and so on cycle-by-cycle.

Third, the substantial exceeding the *dmin*-range over *dmax*-range as well as *tmin*-range over *tmax*-

range (Fig. 1(c)) leads to the following: the majority of unfavourable and damage abnormalities (96%) should be typical for the phenomena towards coldness. And it is confirmed by the observable data (Fig. 4).

Fig. 4 – Unfavourable and damage abnormalities observed in Tomsk over 1991-2012 years.

Generally speaking, the introduced index schemes allow to estimate the potential abilities to forecast the local annual temperature evolution from the viewpoint where the more or less uncertainty in dynamics takes place at least. For example, the

index scheme in Fig. 3(b) exhibits that it is more complicated to make forecasts in Spring (the narrow white gaps in Fig. 3(b)), then in Autumn (the bold white gap in Fig. 3(b)). It confirms both the complexity of forecasts in 1-year timescale [2] and regional differences in the forecast probability [24].

4. CONCLUSION

The local temperature evolution can be so much heterogeneous, that traditional estimations can lose important information. One of the promising directions to develop the traditional estimations is connected with the fractal approach, which allows to extend the knowledge concerning regularities, uncertainties and abnormalities in application to the annual warming-cooling cycle dynamics. In this case the temperature observations are presented as the homogeneous objects (so-called fragments). Thus, the ensemble of traditional, rare considered and unconsidered characteristics of an annual warming-cooling cycle can be used to describe the annual evolution. It allows to exhibit the dominant patterns, in accordance to which the behavior of a local climate system is realized. In particular, it is revealed three main patterns which are observed in more than 70% of all the cases. It is interesting the distribution among these cases: one of the patterns (*the normal pattern*) is observed in more than 50% of cases; each of the rest two patterns (*the auxiliary patterns*) is observed in 25% of cases. The normal pattern is typical for two climatic domains which locate extremely far from each other (the Central European part and the Far East), and the auxiliary patterns are observed between these domains. So, there are, at least, three regions with quite well distinguished and qualitatively different dominants in evolution of the local dynamics. It means that the homogeneity of the dynamics within the regional climatic domains can be rather questionable from the viewpoint of the warming-cooling cycle evolution. At present there are not the established models to explain such facts [3, 4, 5, 23]. Nevertheless, the alternations between the patterns look like rather the behavior under the intermittency phenomena [25]. The main disadvantage of the fractal approach is connected with the comparatively labour data processing, since there are some unformalized analytical procedures with expert opinions.
